Laboratory Exercise 10

An Enhanced Processor

In Laboratory Exercise 1 we described a simple processor. In Part I of that exercise the processor itself was designed, and in Part II the processor was connected to an external counter and a memory unit. This exercise describes subsequent parts of the processor design. The numbering of figures and tables in this exercise are continued from those in Parts I and II of the preceding lab exercise.

In this exercise we will extend the capability of the processor so that the external counter is no longer needed, and so that the processor can perform read and write operations using memory or other devices. A schematic of the enhanced processor is given in Figure 12. In the figure registers r0 to r6 are the same as in Figure 1 of Lab 1, but register r7 has been changed to a counter. This counter is used to provide the addresses in the memory from which the processor's instructions are read; in the preceding lab exercise, a counter external to the processor was used for this purpose. We will refer to r7 as the processor's $program\ counter\ (pc)$, because this terminology is common for real processors available in the industry. When the processor is reset, pc is set to address 0. At the start of each instruction (in time step T_0) the value of pc is used as an address to read an instruction from the memory. The instruction returned from the memory is stored into the IR register and the pc is automatically incremented to point to the next instruction.

The processor's control unit increments pc by using the $incr_pc$ signal, which is just an enable on this counter. It is also possible to load an arbitrary address into pc by having the processor execute an instruction in which the destination register is specified as pc. In this case the control unit uses $r7_{in}$ to perform a load of the counter. Thus, the processor can execute instructions at any address in the memory, as opposed to only being able to execute instructions that are stored at successive addresses. The current content of pc, which always has the address of the next instruction to be executed, can be copied into another register if needed by using a mv instruction.

The enhanced processor will have four new instructions, which are listed in Table 3. The ld (load) instruction reads data into register rX from the external memory address specified in register rY. Thus, the syntax [rY] means that the content of register rY is used as an external address. The st (store) instruction writes the data contained in register rX into the memory address found in rY. The and instruction is similar to the add and sub instructions that were introduced in Lab 1. This instruction extends the adder/subtracter unit in the processor into an arithmetic logic unit. Besides performing addition and subtraction, it has the ability to generate a bit-wise logical AND (&) of the destination register rX with the second operand Op2. As discussed in Lab 1, the operand Op2 can be either another register rY, or immediate data #D.

The $b\{cond\}$ instruction is used to cause a processor branch, which means to change the program counter (pc) to the address of a specific instruction. The cond part of the branch instruction is optional and represents a condition. The instruction loads the constant #Label into pc only if the specified condition evaluates to true. An example of a condition is eq, which stands for equal (to zero). The instruction beq #Label will load the constant Label into pc if the last result produced by the arithmetic logic unit, which is stored in register G, was 0. The $b\{cond\}$ instruction is discussed in more detail in Part V of this exercise.

Operation	Function performed
ld rX, [rY]	$rX \leftarrow [rY]$
st rX, [rY]	$[rY] \leftarrow rX$
and rX, Op2	$rX \leftarrow rX \& Op2$
b{cond} #Label	if (cond), $pc \leftarrow \#Label$

Table 3: New instructions in the enhanced processor.

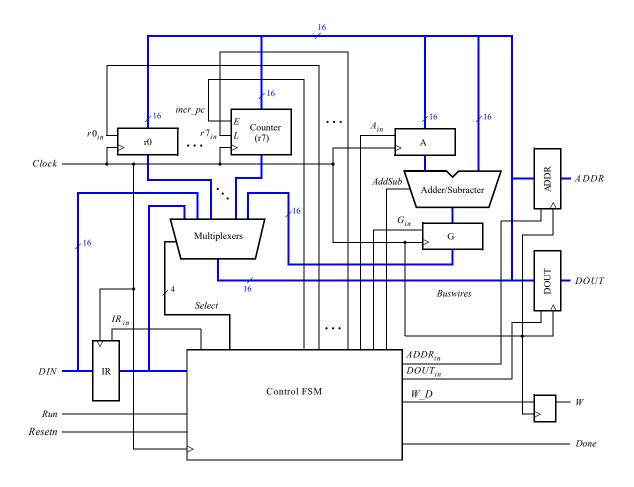

Figure 12: An enhanced version of the processor.

Recall from Lab 1 that instructions are encoded using a 16-bit format. For instructions that specify Op2 as a register the encoding is IIIOXXX000000YYY, and if Op2 is an immediate constant the format is IIIIXXXDDDDDDDD. You should use these same encodings for this exercise. Assume that III = 100 for the Id instruction, 101 for St, 110 for St, and 111 for St?

Figure 12 shows two registers in the processor that are used for data transfers. The *ADDR* register is used to send addresses to an external device, such as a memory unit, and the *DOUT* register is used by the processor to provide data that is to be stored outside of the processor. One use of the *ADDR* register is for reading, or *fetching*, instructions from memory; when the processor wants to fetch an instruction, the content of *pc* is transferred across the bus and loaded into *ADDR*. This address is provided to the memory.

In addition to fetching instructions, the processor can read data at any address by using the ADDR register. Both data and instructions are read into the processor on the DIN input port. The processor can write data for storage at an external address by placing this address into the ADDR register, placing the data to be stored into its DOUT register, and asserting the output of the W(Write) flip-flop to 1.

Connecting the Processor to External Devices

Figure 13 illustrates how the enhanced processor can be connected to memory and other devices. The memory unit in the figure is 16-bits wide and 256-words deep. A diagram of this memory is given in Figure 14. It supports both read and write operations and therefore has both address and data inputs, as well as a write-enable input. As

depicted in Figure 14, the memory has a clock input that is used to store the address, data, and write enable inputs into registers. This type of memory unit is called a *synchronous* static random access memory (SSRAM).

Figure 13 also includes a 9-bit output port (register) that can be used to store data from the processor. In the figure this output port is connected to a set of LEDs, like the ones available on the DE1-SoC board. To allow the processor to select either the memory unit or output port when performing a write operation, the circuit includes address decoding, which is done using NOR gates and AND gates. If the processor's upper address lines $A_{15}A_{14}A_{13}A_{12} = 0000$, then the memory unit can be written. Figure 13 shows n lower address lines connected from the processor to the memory; since the memory has 256 words, then n = 8 and the memory's address port is driven by the processor address lines $A_7 \dots A_0$. For addresses in which $A_{15}A_{14}A_{13}A_{12} = 0001$, the data written by the processor is loaded into the output port connected to LEDs in Figure 13.

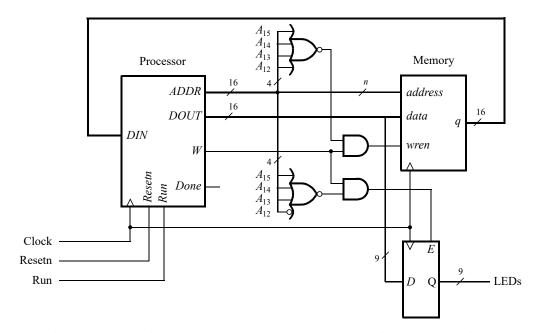

Figure 13: Connecting the enhanced processor to a memory unit and output register.

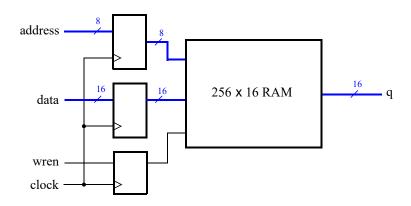

Figure 14: The synchronous SRAM unit.

Part III

Figure 15 gives VHDL code for a top-level file that you can use for this part of the exercise. The input and output ports for this entity are chosen so that it can be implemented on a DE1-SoC board. The VHDL code corresponds to the circuit in Figure 13, plus an additional input port that is connected to switches $SW_8 \dots SW_0$. This input port can be read by the processor at addresses in which $A_{15} \dots A_{12} = 0011$. (Switch SW_9 is not a part of the input port, because it is dedicated for use as the processor's Run input.) To support reading from both the SW input port and the memory unit, the top-level circuit includes a multiplexer that feeds the processor's DIN input. This multiplexer is described by using an if-else statement inside the PROCESS block in Figure 15.

The code in Figure 15 is provided with this exercise, along with a few other source-code files: *flipflop.v*, *inst_mem.v*, *inst_mem.w*, and (part of) *proc.v*. The *inst_mem.v* source-code file was created by using the Quartus IP Catalog to instantiate a RAM: 1-PORT memory unit. It has a 16-bit wide read/write data port and is 256-words deep, corresponding to Figure 14.

```
ENTITY part3 IS
   PORT ( KEY
                      : IN STD_LOGIC_VECTOR(0 DOWNTO 0);

       SW_req);
END Behavior:
```

Figure 15: VHDL code for the top-level file.

The VHDL code in the proc.v file implements register r7 as a program counter, as discussed above, and includes a number of changes that are needed to support the new ld, st, and, and $b\{cond\}$ instructions. In this part you are to augment this VHDL code to complete the implementation of the ld and st instructions, as well as the and instruction. You do not need to work on the $b\{cond\}$ instruction for this part.

Perform the following:

1. Extend the code in *proc.v* so that the enhanced processor fully implements the *ld*, *st*, and *and* instructions. Test your VHDL code by using the ModelSim simulator. Sample setup files for ModelSim, including a testbench, are provided along with the other files for this exercise. The sample testbench first resets the processor system and then asserts the *Run* switch, *SW*₉, to 1. A sample program to test your processor is also provided, in a file called *inst_mem.mif*. This file represents the assembly-language program shown in Figure 16, which tests the *ld* and *st* instructions by reading the values of the SW switches and writing these values to the LEDs, in an endless loop. At the beginning of a simulation, ModelSim loads the contents of the file *inst_mem.mif* into the *inst_mem* memory unit, so that the program can be executed by the processor. Examine the signals inside your processor, as well as the external LEDR values, as the program executes within the ModelSim simulation.

An assembler software tool, called sbasm.py, can be used with your processor. The Assembler is written in Python and is available at https://github.com/profbrown/sbasm.git. To use this Assembler you have to first install Python (version 3) on your computer. The Assembler includes a README file that explains how to install and use it. The sbasm.py Assembler can generate machine code for all of the processor's instructions. The provided file inst_mem.mif was created by using sbasm.py to assemble the program in Figure 16. As the figure indicates, you can define symbolic constants in your code by using the .define directive, and you can use labels to refers to lines of code, such as MAIN. Comments are specified in the code by using //. The assembler ignores anything on a line following //.

Figure 16: Assembly-language program that uses *ld* and *st* instructions.

An example result produced by using *ModelSim* for a correctly-designed circuit is given in Figure 17. It shows the execution of the first four instructions in Figure 16.

2. Once your simulation results are correct, use the Quartus Prime software to implement your VHDL code on a DE1-SoC board. A sample Quartus project file, *part3.qpf*, and Quartus settings file, *part3.qsf*, are provided with the exercise. Compile your code using the Quartus software, and download the resulting circuit into the DE1-SoC board. Toggle the SW switches and observe the LEDs to test your circuit.

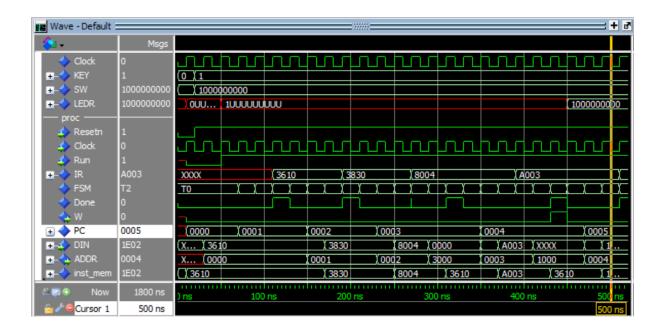

Figure 17: Simulation results for the processor.

Part IV

In this part you are to create a new VHDL entity that represents an output port called *seg7*. It will allow your processor to write data to each of the six 7-segment displays on a DE1-SoC board. The *seg7* entity will include six write-only seven-bit registers, one for each display. Each register should directly drive the segment lights for one seven-segment display, so that the processor can write characters onto the displays.

Perform the following:

- 1. A top-level file is provided for this part called *part4.v*. The top-level entity has output ports for connecting to each of the 7-segment displays. Pin assignments for these ports, which are called *HEX0*[6:0], *HEX1*[6:0], ..., *HEX6*[6:0], are included in the Quartus settings file *part4.qsf*. For each display, segment 0 is on the top of the display, and then segments 1 to 5 are assigned in a clockwise fashion, with segment 6 being in the middle of the display.
 - The part4.v VHDL code includes address decoding for the new seg7 module, so that processor addresses in which $A_{15}A_{14}A_{13}A_{12} = 0010$ select this module. The intent is that address 0×2000 should write to the register that controls display HEXO, 0×2001 should select the register for HEXI, and so on. For example, if your processor writes 0 to address 0×2000 , then the seg7 module should turn off all of the segment-lights in the HEXO display; writing $0 \times 7f$ should turn on all of the lights in this display.
- 2. You are to complete the partially-written VHDL code in the file *seg7.v*, so that it contains the required six registers—one for each 7-segment display.
- 3. You can compile and test your VHDL code by using the ModelSim setup files that are provided for this part of the exercise. An *inst_mem.mif* file is also provided that corresponds to the assembly-language program shown in Figure 18. This program works as follows: it reads the SW switch port and lights up a seven-segment display corresponding to the value read on SW_{2-0} . For example, if $SW_{2-0} = 000$, then the digit 0 is shown on HEX0. If $SW_{2-0} = 001$, then the digit 1 is displayed on HEX1, and so on, up to the digit 5 which would be shown on HEX5 if $SW_{2-0} = 101$.
- 4. Once your simulation results look correct, you should compile the provided Quartus project, and then download and test the circuit on a DE1-SoC board.

```
.define HEX_ADDRESS 0x2000
.define SW_ADDRESS 0x3000
// This program shows the digits 543210 on the HEX displays. Each digit has to
// be selected by using the SW switches.
                            // return address for subroutine
            r5, pc
       mv pc, #BLANK // call subroutine to blank the HEX displays
       mvt r2, #HEX_ADDRESS // point to HEX port
MATN:
        mv r3, #DATA // used to get 7-segment display pattern
        mvt r4, #SW_ADDRESS // point to SW port
        ld r0, [r4] // read switches and r0, #0x7 // use only SW2-
                            // use only SW2-0
        add r2, r0
                            // point to correct HEX display
        add r3, r0
                            // point to correct 7-segment pattern
        ld r0, [r3]
                           // load the 7-segment pattern
            r0, [r2]
                            // light up HEX display
        mv
             pc, #MAIN
// subroutine BLANK
// This subroutine clears all of the HEX displays
// input: none
// returns: nothing
// changes: r0 and r1. Register r5 provides the return address
BLANK: mv r0, \#0 // used for clearing
       mvt r1, #HEX_ADDRESS // point to HEX displays
       st r0, [r1] // clear HEX0
        add r1, #1
                          // clear HEX1
       st r0, [r1]
        add r1, #1
        st r0, [r1]
                            // clear HEX2
        add r1, #1
            r0, [r1]
                            // clear HEX3
        st
        add r1, #1
                          // clear HEX4
        st
             r0, [r1]
        add r1, #1
                            // clear HEX5
        st r0, [r1]
        add r5, #1
                            // return from subroutine
        mv pc, r5
                            // '0'
DATA:
       .word 0b00111111
                             // '1'
        .word 0b00000110
        .word 0b01011011
                             // '2'
                             // '3'
        .word 0b01001111
                             // '4'
        .word 0b01100110
                             // '5'
        .word 0b01101101
```

Figure 18: Assembly-language program that tests the seven-segment displays.

Part V

In this part you are to enhance your processor so that it implements the $b\{cond\}$ instruction. The *conditions* supported by the processor are called eq, ne, cc, and cs, which means that the variations of the branch instruction are b, beq, bne, bcc, and bcs. The b instruction always branches. For example, b #MAIN loads the address MAIN into the program counter. The meanings of the conditional versions are explained below.

The instruction beq means branch if equal (to zero). This instruction performs a branch operation (i.e., loads the provided #LABEL into the program counter) if the most recent result of an instruction executed using the arithmetic logic unit (ALU), which is stored in register G, was 0. Similarly, bne means branch if not equal (to zero). It performs a branch only if the contents of G are not equal to 0. The instruction bcc stands for branch if carry clear. It branches if the last add/subtract operation did not produce a carry-out. The opposite branch condition, bcs, branch if carry set, performs a branch if the most recent add/sub generated a carry-out. To support the conditional branch instructions, you should create two condition-code flags in your processor. One flag, c, should have the value 1 when the ALU generates a result of zero; otherwise c should be 0. The other flag, c, should be 1 when the adder/subtracter in the ALU produces a carry-out; otherwise c should be 0. Thus, c should be 1 when an add instruction generates a carry-out, or when a c operation requires a borrow for the most-significant bit. Your FSM controller should examine these flags in the appropriate clock cycles when executing the c of c of c instructions.

The branch instructions are encoded using the format III1XXXDDDDDDDD, where DDDDDDDDD is the branch address and XXX is the branch condition. Assume that conditions are encoded as *none* (always branch) = 000, eq = 001, ne = 010, cc = 011, and cs = 100.

Perform the following:

1. Enhance your processor so that it implements the condition-code flags z and c, and supports the b[cond] instruction. To help with testing and debugging of your processor, setup files for ModelSim are provided, including a testbench. It simulates your processor instantiated in the top-level file part5.v, which is the same as the one from Part IV. An example $inst_mem.mif$ file is also provided, which corresponds to the program in Figure 19. This program is quite short, which makes it suitable for visual inspection of the waveforms produced by a ModelSim simulation. The program uses a sequence of instructions that test the various conditional branches. If the program reaches the line of code labelled DEAD, then at least one instruction has not worked properly. An example of ModelSim output for a correctly-working processor is given in Figure 20. It shows the processor executing instructions near the end of the code in Figure 19. The instruction that is completed at simulation time 1030 ns is add r0, #1 (0x5001). As shown in the figure, this instruction causes the carry flag, c, to become 1. The next instruction loaded into IR, at time 1090 ns, is bcs #0xC (0xF80C). Finally, the instruction loaded at 1170 ns is b #0 (0xF000).

```
r0, #2
MAIN:
         m\7
LOOP:
         sub
                r0, #1
                               // subtract to test bne
         bne
                #LOOP
         bea
                #T1
                                // r0 == 0, test beg
         mv
                pc, #DEAD
T1:
                r0, #0xFF00
         mv/t
                                // r0 = 0xFFFF
          add
                r0, #0xFF
                                // carry = 0, test bcc
         bcc
                #T2
         mν
                pc, #DEAD
T2:
         add
                r0, #1
                               // carry = 1, test bcs
         bas
                #T3
                pc, #DEAD
         mν
T3:
         b
                #MATN
DEAD:
         m v
                pc, #DEAD
```

Figure 19: Assembly-language program that uses various branches.

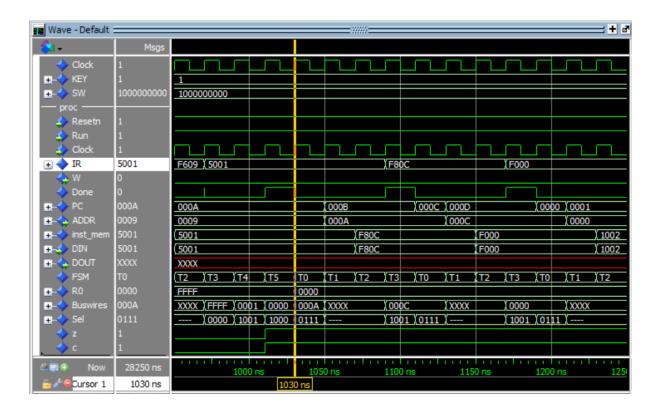

Figure 20: Simulation results for the processor.

2. Once your ModelSim simulation indicates a correctly-functioning processor you should implement it on a DE1-SoC board. A Quartus project file *part5.qpf* and settings file *part5.qsf* are provided for this purpose. To test your processor, you can use the assembly-language program displayed in Figure 21. It provides code that tests for the correct operation of instructions supported by the enhanced processor. If all of the tests pass, then the program shows the word PASSEd on the seven-segment displays. It also shows a binary value on the LEDs that represents the number of successful tests performed. If any test fails, then the program shows the word FAILEd on the seven-segment displays and places on the LEDs the address in the memory of the instruction that caused the failure. Assemble the program, which is provided in a file called *sitbooboosit.s*, by using the *sbasm.py* assembler.

Use the output produced by *sbasm.py* to *overwrite* the file *inst_mem.mif* that you used in the beginning of this part of the exercise to simulate your processor system with ModelSim. Open the Quartus software, compile the *part5* project, and download it onto your DE1-SoC board. If the *Run* signal is asserted, then your processor should execute the *sitbooboosit* program. If a failure is encountered, then the offending instruction can be identified by cross-referencing the LED pattern with the addresses in the file *inst_mem.mif*.

```
.define LED ADDRESS 0x1000
.define HEX_ADDRESS 0x2000
          mν
                r2, #0
                              // used to count number of successful tests
                r6, #T1
                              // save address of next test
          mν
                r0, r0
          sub
                              // set the z flag
T1:
          bne
                #FAIL
                              // test bne; should not take the branch!
                r6, #C1
                              // save address of next test
          m<sub>37</sub>
C1:
          bea
                #C2
                              // test beg; should take the branch
          b
                #FAIL
                              // Argh!
C2:
          add
                r2, #2
                              //\ {\it count\ the\ last\ two\ successful\ tests}
```

Figure 21: Assembly-language program that tests various instructions. (Part a)

```
r6, #T2
                            // save address of next test
        mv
T2:

Figure 21: Assembly-language program that tests various instructions. (Part c)

Part VI

Write an assembly-language program that displays a binary counter on the LED port. Initialize the counter to 0, and then increment the counter by one in an endless loop. You should be able to control the speed at which the counter is incremented by using nested delay loops, along with the SW switches. If the SW switches are set to

their maximum value, 0b111111111, then the delay loops should cause the counter to increment slowly enough so that each change in the counter can be visually observed on the LEDs. Lowering the value of the SW switches should make the counter increment more quickly up to some maximum speed.

You can assemble your program by using the <code>sbasm.py</code> assembler, and then run it on your processor system from Part V. To do this, use the output produced by <code>sbasm.py</code> to <code>overwrite</code> the file <code>inst_mem.mif</code> in the folder that holds your Quartus project for Part V. To make use of the new <code>inst_mem.mif</code> file you do not need to completely recompile your VHDL code from Part V. Instead, execute the Quartus command <code>Processing > Update Memory Initialization File</code>, to include the new <code>inst_mem.mif</code> file in your Quartus project. Next, select the Quartus command <code>Processing > Start > Start Assembler</code> to produce a new programming <code>bitstream</code> for your DE1-SoC board. Finally, use the Quartus Programmer to download the new bitstream onto your board. If the <code>Run</code> signal is asserted, your processor should execute the new program.

Part VII

Augment your assembly-language program from Part VI so that counter values are displayed on the seven-segment display port rather than on the LED port. You should display the counter values as decimal numbers from 0 to 65535. The speed of counting should be controllable using the SW switches in the same way as for Part VI. As part of your solution you may want to make use of the code shown in Figure 22. This code provides a subroutine that divides the number in register r0 by 10, returning the quotient in r1 and the remainder in r0. Dividing by 10 is a useful operation when performing binary-to-decimal conversion. The DIV10 subroutine assumes that r6 is set up to be used as a *stack pointer*. Register r2 is saved on the stack at the beginning of the subroutine, and then restored before returning. This is done so that r2 is not unnecessarily changed by the subroutine. A skeleton of the required code for this part is shown in Figure 23.

```
// subroutine DIV10
    This subroutine divides the number in r0 by 10
    The algorithm subtracts 10 from r0 until r0 < 10, and keeps count in r1
   This subroutine assumes that r6 can be used as a stack pointer
    input: r0
   returns: quotient Q in rl, remainder R in r0
DIV10:
              r6, #1
                               // save registers that are modified
              r2, [r6]
                               // save on the stack
              r1, #0
                               // init Q
              r2, #9
DLOOP:
                               // check if r0 is < 10 yet
        mv
        sub r2, r0
        bcc
            #RETDIV
                               // if so, then return
INC:
        add r1, #1
                               // but if not, then increment Q
                               // r0 -= 10
        sub r0, #10
              #DLOOP
                               // continue loop
RETDIV:
              r2, [r6]
        ld
                               // restore from the stack
        add
              r6, #1
              r5, #1
        add
                               // adjust the return address
                               // return results
              pc, r5
        mν
```

Figure 22: A subroutine that divides by 10

As described previously, assemble your program with *sbasm.py*, update your *MIF* file in the Quartus software, generate a new bitstream file by using the Quartus Assembler, and then download the new bitstream onto your DE1-SoC board to run your new program.

```
.define HEX_ADDRESS 0x2000
.define SW_ADDRESS 0x3000
.define STACK 256
                               // bottom of memory
// This program shows a decimal counter on the HEX displays
            r6, #STACK // stack pointer
                               // return address for subroutine
        mν
            r5, pc
